## About Lesson

# Based on Operation

## Preprogrammed Robots

Pre-programmed robots operate in a controlled environment where they do simple and monotonous tasks. An example of a preprogrammed robot would be a mechanical arm on an automotive assembly line.

## Humanoid Robots

A humanoid robot is a robot with its body shape built to resemble the human body. The design may be for functional purposes, such as interacting with human tools and environments, for experimental purposes, such as the study of bipedal locomotion.

Some humanoid robots also have heads designed to replicate human facial features such as eyes and mouths.

## Teleoperated Robots

Tele-operated robots are remotely controlled robots. They might have some sort of intelligence, but normally they take their command from a human operator and execute exactly as instructed. Right now, tele-operated robots are mostly used in medical surgeries and military operations.

device would be a prosthetic limb or bionic arm

## Autonomous Robots

An autonomous robot is a robot that is designed and engineered to deal with its environment on its own, and work for extended periods of time without human intervention. A truly autonomous robot is one that can perceive its environment, make decisions based on what it perceives and/or has been programmed to recognize conditions and then actuate a movement or manipulation within that environment.

## About Lesson

## Evolution of Robotics

Robotics is now one of humanity's greatest achievements and the single greatest endeavour to create an artificial, sentient entity. The idea of a machine that looks and behaves like a human being goes back at least 2,000 years. According to Greek mythology, Hephaestus, the god of fire, constructed artificial women out of gold. These women were able to walk, talk, and even to think.

The term "robot" comes from a Czechoslovakian word for "work" used in the 1921 play by Karel Čapek called R.U.R. ("Rossum's Universal Robots") to describe an army of manufactured industrial slaves. Since then, we have come to think of robots as the mechanical men or "androids" of modern science fiction.

In reality, technical manuscripts from as early as 300-400 b.c. reveal that humans beings have been trying to build automated machines or "automata" for centuries. The development of modern robotics was precipitated by the advent of steam power and electricity during the Industrial Revolution. A growing market for speed up production drove engineers to devise ways of producing automatic machines to speed up production, do tasks that humans could not do, and to replace humans in dangerous situations.

In 1933 Canadian professor George Moore produced "Steam Man," a prototype for a humanoid robot made of steel and powered by a 0.5 horse-power steam engine. Tesla also wrote that it was possible to someday build an intelligent, anthropomorphic humanoid robot.

Today's robots are built into the automotive industry, the food industry, the pharmaceutical industry, and the military. By the 1950s engineers were developing machines to handle difficult or dangerous repetitive tasks. Because robots were meant to replicate the pattern of movement used in a factory, they were called "unicomats." These were modified versions of the first patents for robotic arms filed over a decade earlier. For example, patents for both the "Position Controlling Apparatus" filed in 1938 by Willard V.

Pollard and a spray-painting apparatus by Karel A. Rosseel, filed in 1930, were needed on human shoulder-arm-wrist configuration and dexterity. Rosseel's design patent was granted to the DeVilbiss Company, which would later become a major supplier of robotic arms in the United States. These early prototypes were not mass-produced. However, once electronic controllers came into use after the Second World War, similar but more efficient designs were developed, including the first computer-controlled revolute arms from Case Western Reserve and General Mills in 1950, and a complex, hydraulically powered robotic arm by the British inventor Cyril W. Kenward, who filed his patent in 1954 and published it in 1957.

By the eighteenth century, scientists and inventors had created an impressive array of mechanical figures that looked and acted like humans and other animals. Swiss watchmaker Pierre Jacquemot (1721-1790), and his son Henri-Louis (1752-1791), for example, designed and constructed animated dolls, called automata, and mechanical birds to help sell watches. One doll was able to play the piano, swing in time with the music, and a young scribe who could write messages of up to 40 characters.

Among the first certifiable automation is a humanoid drawn by Leonardo da Vinci (1452-1519) in around 1480. Leonardo's notebooks, rediscovered in the 1950s, contain detailed drawings of a mechanical knight in armor which was able to step forward, wave its arms and move its head. In 1938, Georges Devol and Joseph Engelberger, two engineers from France, invented the first hydraulic robot arm. This arm, which was hydraulically-powered, was first used by a team of researchers to move objects around obstacles. More recent models, like the RoboArm, Sweepers and Recycling Scrubbers from the Serius Robots Company, have the area to be cleaned by themselves. They operate independently, without reference targets, and have built-in obstacle detection and avoidance protocols.

Robots have cleared more than offices; they have been used for larger, environmental hazard jobs, such as the cleanup at Chernobyl nuclear power plant in the Soviet Union, following a major radioactive explosion there in 1986. Shokley's ability to learn from interaction of its sensors with the environment also became the basis for the small, insect-like robots developed by researchers such as Rodney Brooks of the Massachusetts Institute of Technology (MIT) beginning in the 1980s.

Brooks believed that the interaction of machine sensors with their environment creates a learning situation for robots similar to that of a human infant. According to this theory, it is not necessary to build complex computers with thousands of stored rules to control the robot. Instead, simple motor and sensor elements are combined to create robots that learn from experience. Brooks built robots modeled on multi-legged insects such as "Genghis"—designed to negotiate the kind of rough terrain that would be encountered on other planets. NASA planned to use "Hermes," a smaller version of Genghis, to explore the surface of Mars. Many researchers argue that a human robot is best to interact with the human body in a natural way. The projected use for Genghis is to perform as an in-home care-giver. Other university-based robotics research in the United States, including projects at the University of Southern California, the University of California-Berkeley, and Georgia Tech are destined for use in medical, private and military security capacities, or in environmental hazard situations. U.S. and European robotics research is tackling issues such as mobility, robot-human interaction, vision systems, speech imitation and recognition, and cognition. These topics are nothing new to Japanese robot designers.

Japan, which has almost twice as many robots as the United States, is developing android type robots for wide-ranging uses—to work outside of space stations and spacecraft, to interact with its growing geriatric population in hospitals and at home, and to act as civil servants in urban centers. By 1986 the Honda Motor Company had completed "P-1," which meant to "coexist and cooperate with human beings." Honda expected that by the time their humanoid robot was perfected, such robots would be used in everyday life to serve humans, not just in special operations. In the fall of 1997 Honda completed "P-3," which looks like a suited astronaut. It had a vision sensor (a motorized camera and range-finder) positioned above a central processing unit (computer) on the chest. Shokley was propelled by two methods of problem solving that allowed it to recognize the shape of objects, push them, and negotiate a ramp. Like Shokley's service robots of the 1980s, were essentially "brains in a box" that can plug into mapped pathways laid out on the floor and could recognize and maneuver around obstacles. More recent models, like the RoboArm, Sweepers and Recycling Scrubbers from the Serius Robots Company, have the area to be cleaned by themselves. They operate independently, without reference targets, and have built-in obstacle detection and avoidance protocols.

## About Lesson

# Introduction to Robotics

Welcome to robotics! We're glad you found us.

Technology has changed our lives in countless ways, but it can also change them for the better. Robotics technology is expected to be one of the 21st century's greatest disruptors, helping us work more efficiently and even survive on other planets. Robotics is a field of science working with machines that perform tasks based on predetermined and adaptive programs and algorithms in an automatic or semi-automatic way. These machines – commonly called robots – are either controlled by humans or work entirely under the supervision of a computer application and algorithms. Robotics is a comprehensive concept that includes the building, planning and programming of robots. These robots are in direct contact with the physical world – and they have often been used to perform monotonous and repetitive tasks instead of human beings. Robotics technology has grown exponentially, making it possible for us to develop some amazing applications. From driverless cars to medical robots that can perform surgery and even detect skin cancer, these are just a few of the ways robotics is changing the world.

Robotics is the intersection of science, engineering and technology that produces machines called robots that substitute or replicate human actions

Since the beginning of time, people have wanted to build machines that could do things with technology.

Robotics is the study and development of the theory, design, construction, operation and application of autonomous agents that can perceive their environment and react to it.

Robotics involves understanding how a system works, such as its components or how it interacts with other systems. These include sensors that measure environmental conditions and computing systems that process information from those sensors.

Robotics is an important part of modern industry as it has been widely used in manufacturing processes. Robotics helps produce goods faster and more efficiently than human workers. In addition to this, robots have been used in many fields such as military technology, social sciences and even entertainment.

## About Lesson

# Characteristics of SCARA Robots

Some SCARA characteristics like high reliability, high accuracy and speed, minimum maintenance, ease of use and extremely compact design make this kind of robot really suitable to work; the composed system guarantees high performances in term of productivity and, at the same time, high flexibility in assembly lines and production systems. Also it does not require any retooling cost for product changeovers: product changes can be made in a matter of seconds without any trouble.

## Advantages of SCARA robots

- Generally, a SCARA robot can operate at a higher speed and with options like cleanroom specifications.
- The SCARA robot is commonly used for pick-and-place or assembly operations when high speed and high accuracy are required.
- SCARA Robots currently available can achieve tolerances lower than 10 microns. This tolerances can be compared to 20 microns for a six-axis robot.
- The compact layout of SCARA Robots also makes them more easily re-located in temporary or remote applications: by design, the SCARA robot suits applications with a smaller field of operation and where floor space is limited.
- Higher Payload: Typically, they carry up to 2 kg nominal (6 kg maximum).
- The envelope of a SCARA robot is typically circular, which doesn't suit all applications, and the robot has limited dexterity and flexibility compared to the full 3D capability of other types of robots (e.g. six-axis robots).

## About Lesson

The SCARA acronym stands for Selective Compliance Assembly Robot Arm or Selective Compliance Articulated Robot Arm.

The robot was developed under the guidance of Hiroshi Makino, a professor at the University of Yamanashi. The arms of SCARA are flexible in the XY-axes and rigid in the Z-axis that makes it to familiarize to holes in the XY-axes.

Scara is a type of Industrial robot.

The SCARA robot is most commonly used for pick-and-place or assembly operations where high speed and high accuracy is required. Generally a SCARA robot can operate at higher speed and with optional cleanroom specification.

Industrial robots are defined as 'multi-functional manipulators designed to move parts through various programmed motions'. As such, robots provides **consistent reliable performance, repetitive accuracy** and are able to handle heavy work loads and perform in harsh environments. Additionally, robots can be **quickly reprogrammed** to reflect changes in production needs and cycles.

## About Lesson

# Applications for Cartesian Robots

The versatility, lower cost, and ease of programming make Cartesian robots viable for many applications in industrial settings. Let us have a look at some of them.

- **Pick and place:** The robotic arm is fitted with some variation of vision device to identify different components from a carousel or conveyor belt. The arm can pick these objects and sort them into different bins. Picking and sorting can be done by a single robotic arm.
- **Process-to-process transfer:** In a production line there will be instances where goods in the process need to be transferred from one location to another. It can be done using dual-drive linear robots. They can be used with vision systems or time-synchronization depending on the rest of the process.
- **Assembling system:** When the same steps have to be repeated over and over to assemble the parts of a product, linear robots can be used to automate the tasks.
- **Application of adhesives and sealants:** Many production processes involve the application of adhesives or sealants between parts. It is used in large automobile manufacturing to small electronic gadget production. Adhesives and sealants are to be
- **Palletizing and depalletizing:** Packing uses pallets to transport goods with ease. Cartesian robots can be used to automate both placing products on pallets and taking them from pallets.
- **CNC machine tooling:** Computer numeric controls-based machines are used to create products according to designs made in engineering design software. CNC machines widely use linear robots with different tools attached to the robotic arms.
- **Precision spot welding:** Specialized welding is required in certain manufacturing processes. Linear robots with welding arms can achieve accurate welds in precise locations on the work surface. The high level of tolerance in the micrometers ( $\mu\text{m}$ ) range is helpful in such applications.

## About Lesson

## Characteristics and Advantages

Cartesian robots have a higher payload carrying capacity compared to their equivalent six-axis robots. This, combined with the lower cost and ease of programming for linear robots, makes them suitable for a large variety of industrial applications. Gantry robots, which are essentially Cartesian robots with supporting scaffolding, can carry even higher payloads. The range of movement for linear robots can be extended by adding compatible modules to the existing mechanism. This modularity in Cartesian robots makes them much more versatile and has a longer life in an industrial setting.

Cartesian robots also exhibit a high level of accuracy and precision compared to their rotary counterparts. This is due to the fact that they only have linear motion and no need to accommodate rotary motion. Cartesian robots can have tolerances in the range of micrometers ( $\mu\text{m}$ ), whereas six-axis robots generally have tolerances in the range of millimeters (mm).

## About Lesson

# How Do Cartesian Robots Function

Cartesian robots only move through linear motion, generally through servomotor drives. The linear actuators used can be in various forms according to the specific application. The drive system can be belt-driven, cable-driven, screw-driven, pneumatic-driven, rack-and-pinion-driven, or linear-motor-driven. Some manufacturers provide completely pre-made Cartesian robots that can be implemented without any modifications. Other manufacturers offer different components as modules, allowing the user to implement a combination of these modules according to their specific use case.

The robotic arms themselves can be equipped with "vision" or can be "blind" in operations. They can be attached to light sensors or cameras to identify the objects before executing an action. For example, Cartesian robots can be used in laboratories to pick and move samples. Computer-aided vision can be used to recognize the test tube, pipettes, or slides and the arm can grab the object according to the position data conveyed from the camera.

The advantage of Cartesian robots over other robotic systems, like six-axis robots, is that they are very easy to program. A single motion controller can handle the movement logic for a Cartesian robot. The robots have only linear motion, enabling ease of control. There is

## About Lesson

## Cartesian Robots

Mechatronic robots that use linear axes for movement are called Cartesian robots, linear robots, or gantry robots. Gantry robots look similar to gantry cranes and operate similarly. But gantry robots are not limited to lifting and moving functions. They can have custom functionality as per the requirement.

Cartesian robots have an overhead structure that controls the motion in the horizontal plane and a robotic arm that actuates motion vertically. They can be designed to move in x-y axes or x-y-z axes. The robotic arm is placed on the scaffolding and can be moved in the horizontal plane. The robotic arm has an effector or machine tool attached to the end of the arm depending on the function where it is used.

Though Cartesian robots and gantry robots are used interchangeably, gantry robots generally have two x-axes while Cartesian robots will have only one each of the two/three axes (according to the configuration).

## About Lesson

# Cartesian System

Cartesian coordinate geometry is an excellent method for mapping three-dimensional space in a simple, easy-to-understand numerical system. In the Cartesian system for three-dimensional space, there are three coordinate axes that are perpendicular to each other (orthogonal axes) and meet at the origin.

The three axes are generally referred to as the x-axis, y-axis, and z-axis. Any point in three-dimensional space is represented by three numbers as (x, y, z). X represents the distance of the point from the origin along the x-axis, y is the distance from the origin along the y-axis, and z is the distance from the origin along the z-axis.

## About Lesson

## Applications

- Parallel robots are used in various industrial applications such as:
- Flight simulators
- Automobile simulators
- In work processes
- Photonics / optical fiber alignment

They are used in limit in the workspaces. To perform a desired manipulation, it would be very difficult and can lead to multiple solutions. Two examples of popular parallel robots are the Stewart platform and the Delta robot.

## Advantages

- Very high speed
- Contact lens shaped working envelope
- Excels in high speed, lightweight pick and place applications (candy packaging)

## Disadvantages

It requires dedicated robot controller in addition to line master controller like PLC/PCs

## About Lesson

# Parallel Configuration

Parallel robots are also known as parallel manipulators or generalized Stewart platforms.

A parallel robot is a mechanical system that uses several computer-controlled serial chains to support a single platform, or end-effector.

Furthermore, a parallel robot can be formed from six linear actuators that maintain a movable base for devices such as flight simulators. These robots prevent redundant movements and to carry out this mechanism, their chain is designed to be short, simple.

They are known as:

- High speed and high precision milling machines
- Micro manipulators mounted on the end effector of larger but slower serial manipulators

## About Lesson

# Articulated Robot

An Articulated robot can be defined as a robot with rotary joint and these robots can range from simple two-jointed structures to systems with 10 or more interacting joints.

These robots can reach any point as they work in three dimensional spaces. On the other hand, articulated robot joints can be parallel or orthogonal to each other with some pairs of joints parallel and others orthogonal to each other. As articulated robots have three revolute joints, the structure of these robots is very similar to the human arm.

## About Lesson

# Cylindrical Robots

The base of cylindrical robots has a rotary joint, and the links are connected by prismatic joints. The robots have a cylindrical-shaped work envelop, which is achieved with rotating shaft and an extendable arm that moves in a vertical and sliding motion. Because of their compact design, cylindrical robots are frequently used in small spaces for simple assembly, machine tending, or coating applications.

## About Lesson

# Cylindrical Coordinate System

A cylindrical coordinate system is a **three-dimensional coordinate system** that specifies point positions by the distance from a chosen reference axis, the direction from the axis relative to a chosen reference direction, and the distance from a chosen reference plane perpendicular to the axis. The latter distance is given as a positive or negative number depending on which side of the reference plane faces the point.

The origin of the system is the point where all three coordinates can be given as zero. This is the intersection between the reference plane and the axis.

The axis is variously called the cylindrical or longitudinal axis, to differentiate it from the polar axis, which is the ray that lies in the reference plane, starting at the origin and pointing in the reference direction.

**The distance from the axis may be called the radial distance or radius**, while the angular coordinate is sometimes referred to as the **angular position or as the azimuth**. The radius and the azimuth are together called the polar coordinates, as they correspond to a two-dimensional polar coordinate system in the plane through the point, parallel to the reference plane. The third coordinate may be called the height or altitude (if the reference plane is considered horizontal), longitudinal position, or axial position.

**Cylindrical coordinates** are useful in connection with objects and phenomena that have It is sometimes called '**cylindrical polar coordinate**' and '**polar cylindrical coordinate**', and is sometimes used to specify the position of stars in a galaxy ("galactocentric cylindrical polar coordinate").

## About Lesson

# Polar / Spherical Coordinate Robots

Polar Robots, or spherical robots, have an arm with two rotary joints and one linear joint connected to a base with a twisting joint. The axes of the robot work together to form a polar coordinate, which allows the robot to have a spherical work envelope. Polar Robots are credited as one of the first types of industrial robots to ever be developed. Polar robots are commonly used for die casting, injection molding, welding, and material handling.

In other words, **spherical robot** is a robot with two rotary joints and one prismatic joint; in other words, two rotary axes and one linear axis. Spherical robots have an arm which forms a spherical coordinate system.

## About Lesson

# Spherical Coordinate System

In mathematics, a **spherical coordinate system** is a coordinate system for three-dimensional space where the position of a point is specified by three numbers: the radial distance of that point from a fixed origin, its polar angle measured from a fixed zenith direction, and the azimuth angle of its orthogonal projection on a reference plane that passes through the origin and is orthogonal to the zenith, measured from a fixed reference direction on that plane.

The radial distance is also called the radius or **radial coordinate**. The polar angle may be called colatitude, zenith angle, normal angle, or inclination angle.

## About Lesson

# Important Terms

**Positional Commands:** A robot can perform the required position using a GUI or text based commands in which the essential X-Y-Z position may be specified and edited.

**Teach Pendant:** Using a teach pendant method, we can teach the positions to a robot. Teach pendant is a handheld control and programming unit that contain the capability to manually send the robot to a desired position. A teach pendant can be disconnected after the completion of programming. But, the robot runs the program, which was fixed in controller.

**Lead-by-the-nose:** Lead-by-the-nose is a technique which will be included by many robot manufacturers. In this method, one user holds the robot's manipulator, while another person enters a command that helps to de-energize the robot which will make it to go into limp.

Then, user can move the robot to the required position (by hand) while the software records these positions into memory. Several robot manufacturers use this technique for performing paint spraying.

Name of joint	Representation	Description
Revolute		Allows relative rotation about one axis.
Cylindrical		Allows relative rotation and translation about one axis.
Prismatic		Allows relative translation about one axis.
Spherical		Allows three degrees of rotational freedom about the center of the joint. Also known as a ball-and-socket joint.
Planar		Allows relative translation on a plane and relative rotation about an axis perpendicular to the plane.

## About Lesson

# Links and Joints

The individual bodies that make up a robot are called 'links.' Here, unless otherwise stated, all links are assumed to be rigid, i.e., the distance between any two points within the body does not change while it is moving. A rigid body in the three dimensional Cartesian space has six DOF. This implies that the position of the body can be described by three translational, and the orientation by three rotational coordinates. For convenience, certain non-rigid bodies, such as chains, cables, or belts, which when serve the same function as the rigid bodies, may be considered as links. From the kinematic point of view, two or more members when connected together without any relative motion between them is considered as a single link. For example, an assembly of two gears connected by a common shaft is treated as one link. Links of a robot are coupled by kinematic pairs or joints. A 'joint' couples two links and provides physical constraints on the relative motion between the links. It is not a physical entity but just a concept that allows one to specify how one link moves with respect to another one. For example, a hinge joint of a door allows it to move relative to the fixed wall about an axis. No other motion is possible. Type of relative motion permitted by a joint is governed by the form of the contact surface between the members, which can be a surface, a line, or a point. Accordingly, they are termed as either 'lower' or 'higher' pair joint. If two mating links are in surface contact, the joint is referred to as a lower pair joint. On the contrary, if the links are in line or point contact, the

## About Lesson

# Manipulators & End Effector

A manipulator in robotics is a tool used to move materials without the user making any direct physical touch. Originally, the applications were employed inaccessibly or to handle radioactive or biohazardous objects with robotic arms. In more recent advances, they have been used in a variety of applications, including robotic surgery, welding automation, and space travel.

Manipulators are composed of an assembly of links and joints. Links are defined as the rigid sections that make up the mechanism and joints are defined as the connection between two links. The device attached to the manipulator which interacts with its environment to perform tasks is called the end-effector.

## About Lesson

## What's a robot manipulator ?

A robot manipulator is an electronically controlled mechanism, consisting of multiple segments, that performs tasks by interacting with its environment. They are also commonly referred to as robotic arms. Robot manipulators are extensively used in the industrial manufacturing sector and also have many other specialized applications (for example, the Canadarm was used on space shuttles to manipulate payloads). The study of robot manipulators involves dealing with the positions and orientations of the several segments that make up the manipulators.

## About Lesson

# Classification based on Kinematic Structure

## Open-loop manipulator (or serial robot):

A manipulator is called an open-loop manipulator if its links form an open-loop chain.

## Parallel manipulator:

A manipulator is called a parallel manipulator if it is made up of a closed-loop chain.

## Hybrid manipulator:

A manipulator is called a hybrid manipulator if it consists of open loop and closed loop chains

## About Lesson

# Classification based on Motion Characteristics

**Planar Manipulator:**

A manipulator is called a planar manipulator if all the moving links move in planes parallel to one another.

**Spherical Manipulator:**

A manipulator is called a spherical manipulator if all the links perform spherical motions about a common stationary point.

**Spatial Manipulator:**

A manipulator is called a spatial manipulator if at least one of the links of the mechanism possesses a general spatial motion.

## About Lesson

## What is DOF?

The term degrees of freedom is widely used to define the motion capabilities of robots, including androids (humanoid robots). In this context, the term generally refers to the number of joints or axes of motion on the robot.

The number of degrees of freedom of a mechanism are defined as the number of independent variables that are required to completely identify its configuration in space. The number of degrees of freedom for a manipulator can be calculated as:

$$n_{dof} = \lambda(n - 1) - \sum_{i=1}^k (\lambda - f_i)$$

... Eq. (1)

where  $n$  is the number of links (this includes the ground link),  $k$  is the number of joints,  $f_i$  is the number of degrees of freedom of the  $i^{th}$  joint and  $\lambda$  is 3 for planar mechanisms and 6 for spatial mechanisms.

# Motor Driver

As the name suggest a motor driver IC or module is used to drive the motors of a robot. We are using it as a kind of protection from high voltages which would damage our microcontroller board which in this case is our Space Robochip.

Its because our microcontroller board only require maximum of 5v to run but for motors we need more voltage for its proper working. So we use this driver as a link to carry out both the jobs together, which is the proper working of microcontroller board as well as the motors

## About Lesson

## Documentation – Motor Driver

As the name suggest a motor driver IC or module is used to drive the motors of a robot. We are using it as a kind of protection from high voltages which would damage our microcontroller board which in this case is our Space Robochip.

Its because our microcontroller board only require maximum of 5v to run but for motors we need more voltage for its proper working. So we use this driver as a link to carry out both the jobs together, which is the proper working of microcontroller board as well as the motors

# Ultrasonic Sensor

An **ultrasonic sensor** is an electronic device that measures the distance of a target object by emitting **ultrasonic** sound waves. Usually a normal ultrasonic sensor will have 4 pins. In order to generate the ultrasound we need to set the **Trigger Pin** on a **High State** for **10 microseconds**. That will send out an 8 cycle sonic burst which will travel at the speed of sound and it will be received in the Echo Pin. The Echo Pin will **output** the **time** in microseconds the sound wave traveled.

## Experiment Connections:

## About Lesson

## Documentation – Ultrasonic Basics

An ultrasonic sensor is an electronic device that measures the distance of a target object by emitting ultrasonic sound waves. Usually a normal ultrasonic sensor will have 4 pins.

In order to generate the ultrasound we need to set the Trigger Pin on a High State for 10 microseconds. That will send out an 8 cycle sonic burst which will travel at the speed of sound and it will be received in the Echo Pin. The Echo Pin will output the time in microseconds the sound wave traveled.

## Experiment Connections:

- Vcc to 5V of Space Robochip
- Trig to Digital Pin 5 of Space Robochip
- Echo to Digital Pin 6 of Space Robochip
- GND to GND of Space Robochip

## Code:

```
const int trigPin = 5;
const int echoPin = 6;

float duration, distance;

void setup() {
pinMode(trigPin, OUTPUT);
pinMode(echoPin, INPUT);
Serial.begin(9600);
}

void loop() {
digitalWrite(trigPin, LOW);
delayMicroseconds(2);
digitalWrite(trigPin, HIGH);
delayMicroseconds(10);
digitalWrite(trigPin, LOW);

duration = pulseIn(echoPin, HIGH);
distance = (duration*.0343)/2;
Serial.print("Distance: ");
Serial.println(distance);
delay(100);
}
```

# Code - LED Blink

```
void setup() {
    pinMode(6, OUTPUT);
}
void loop(){
    digitalWrite(6, HIGH);
    delay(100);
    digitalWrite(6, LOW);
    delay(100);
}
```

## About Lesson

### Library – LED Experiment

A light-emitting diode (LED) is a semiconductor device that emits light when an electric current is passed through it.

In this experiment we have connected the positive end to digital pin 6 of our microcontroller board. As well as we will connect the negative pin of LED to GND of our microcontroller board.

Positive(+) to Digital Pin 6

Negative(-) to GND

### Code:

```
void setup() {
    pinMode(6, OUTPUT);
}
void loop(){
    digitalWrite(6, HIGH);
    delay(100);
    digitalWrite(6, LOW);
    delay(100);
}
```
